# Skewed Classes

- **Skewed** classes (dataset is imbalanced): when there is **no sufficient training** examples **for one of the classes**
  - For example in the default data set, **3%** of the training examples actually defaulted and **97%** did not.
    - In this case, a trivial classifier that always predicts that an individual will not default will have error rate of 3% (relatively good)
- Another example: assume that email spam detection system has data set with only **1%** of emails are spam..
  - Predicting all emails are not spam would lead to 99% accuracy (or 1% error rate)

Ref: <https://sci2s.ugr.es/imbalanced>

# Performance Measures

- Thus, error rate (or accuracy) is not sufficient evaluation metric when classes are skewed
- Other metrics are more convenient: confusion matrix, precision, recall, ..
- These measures are also helpful to analyze the performance of classifiers even if classes are not skewed (have balanced dataset)

# Confusion Matrix

- Assume two classes: negative class (Null) & positive class (Non-null)
  - For imbalanced dataset - Assume Positive class is the rare class

|                   |               | <i>Predicted class</i> |                 |
|-------------------|---------------|------------------------|-----------------|
|                   |               | – or Null              | + or Non-null   |
| <i>True class</i> | – or Null     | True Neg. (TN)         | False Pos. (FP) |
|                   | + or Non-null | False Neg. (FN)        | True Pos. (TP)  |

- True negative (TN): # correctly classified samples belonging to negative class
- False positive (FP): # samples in negative class misclassified as positive
- False negative (FN): # samples in positive class misclassified as negative
- True positive (TP): # correctly classified samples belonging to positive class

# Confusion matrix

|                |                    |                    |
|----------------|--------------------|--------------------|
| negative class | <b>TN</b>          | <b>FP</b>          |
| positive class | <b>FN</b>          | <b>TP</b>          |
|                | predicted negative | predicted positive |

Some of samples predicted negative  
are true/correct (TN) or false (FN):

Some of samples predicted as  
positive are true (TP) or false (FP)

# Example: Imbalanced DataSet

- Dataset in sklearn (load\_digits) contains digits from 0 – 9
- Suppose you want to build a classifier that classifies digit 9 (against the remaining digits 0 – 8)
  - Your prediction is either the digit is 9 or not
  - You created an **imbalanced dataset**
    - Since number of times where 9 appears is much less than the number of times the other digits appear
  - A dummy classifier that selects majority (not 9) will have accuracy around 90%

# Example .. cont

Confusion Matrix of Logistic Regression (C=0.1)

|                 |                      |                  |
|-----------------|----------------------|------------------|
| true 'not nine' | 401                  | 2                |
| true 'nine'     | 8                    | 39               |
|                 | predicted 'not nine' | predicted 'nine' |

Positive class is the rare class

# Example: Apply LDA to Credit Card Default Data Set

- Objective: predict whether or not an individual will default (i.e., 2 classes: default, not default)
  - Two features ( $p=2$ ): **income** and **balance** on the credit card
  - Dataset contains information of  **$n=10,000$**  individuals
- Confusion matrix (here applied on training data for illustration, in real-world we do not use training for evaluation)

|                     |     | Predicted default status |     |                             |
|---------------------|-----|--------------------------|-----|-----------------------------|
|                     |     | No                       | Yes |                             |
| True default status | No  | 9644                     | 23  | Total not defaulted=9667    |
|                     | Yes | 252                      | 81  | Total actual defaulted =333 |

LDA is applied here

# Modify the classifier could help!

- We can modify the classifier to do better job
- For example: with LDA we use Bayes rule and, we predict an individual will default if:

$$P(\text{default} = \text{Yes} | X = x) > P(\text{default} = \text{No} | X = x) .$$

This is equivalent to deciding that an individual will default if:

$$\Pr(\text{default} = \text{Yes} | X = x) > 0.5$$

Note that:  $P(\text{default} = \text{Yes} | X = x) + P(\text{default} = \text{No} | X = x) = 1$

- We can modify the classifier by changing the 0.5 threshold!

# Example

- If credit card company wants to avoid incorrectly classifying an individual who will default (& sees misclassification of not default to be less problematic)
  - Then can lower the threshold:

$$\Pr(\text{default} = \text{Yes} | X = x) > 0.2$$

The resulted confusion matrix in this case is:

|                     |     | Predicted default status |            |
|---------------------|-----|--------------------------|------------|
|                     |     | No                       | Yes        |
| True default status | No  | <b>9432</b>              | <b>235</b> |
|                     | Yes | <b>138</b>               | <b>195</b> |

# Precision and Recall

- **Precision:** Out of the all classes that we **predicted positive**, what fraction is actually positive

$$\begin{aligned} \text{Precision} &= \frac{\text{True positive}}{\text{All predicted positives}} \\ &= \frac{\text{True positive (TP)}}{\text{True Positive (TP) + False Positive (FP)}} \end{aligned}$$

**Positive class is the rare class**

# Precision and Recall

- **Recall (detection accuracy, true positive rate, sensitivity):**  
Out of all the **actual positive** examples, what fraction we correctly detect as positive

$$\begin{aligned} \text{Recall} &= \frac{\text{True positive}}{\text{Actual positives}} \\ &= \frac{\text{True positive (TP)}}{\text{True Positive (TP) + False Negative (FN)}} \end{aligned}$$

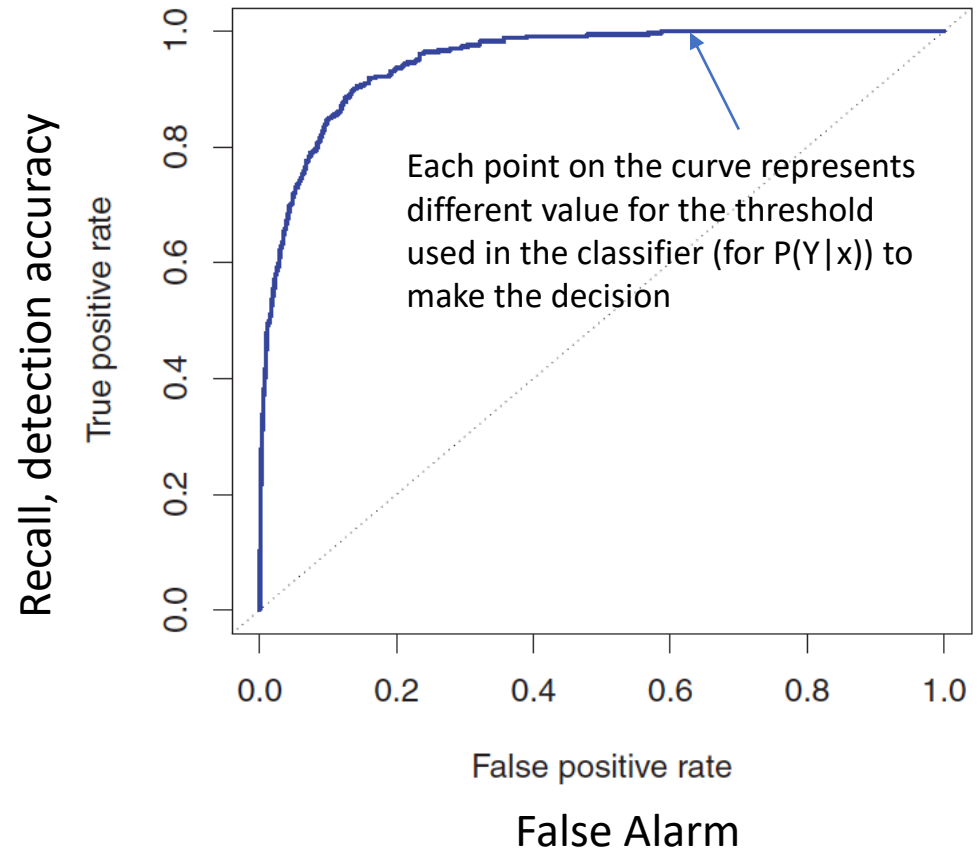

# Precision and Recall

- Positive class is the rare class, we need to detect with high accuracy
- It is desired to have high precision and recall
- Other metrics:
  - **F-score** =  $2 * \text{precision} * \text{recall} / (\text{precision} + \text{recall})$
  - **False positive rate (FPR)** :  **$\text{FPR} = \text{FP} / (\text{FP} + \text{TN})$**
  - **Specificity** =  $1 - \text{false positive rate} = \text{True negative rate}$

|                |                    |                    |
|----------------|--------------------|--------------------|
| negative class | TN                 | FP                 |
| positive class | FN                 | TP                 |
|                | predicted negative | predicted positive |

# Receiver Operating Characteristics (ROC) Curve

- Curve shows: **false positive rate (FPR)** versus **true positive rate (recall)**
  - **$FPR = FP / (FP + TN)$** 
    - Number of times you **misclassified as positive** divided **by all the negative examples**
- ROC is also used to analyze the behavior of the classifier
  - Each point represent **different threshold** used for classification
  - Largest area under curve (AUC) = 1
- Required: high recall (true positive) and low false positive rate
  - But there is a trade-off between them

# Confusion Matrix for Multiclass Classification

- Similar to two-class classification, average error or accuracy will not be adequate if the data set is **imbalanced datasets**
  - Example: Assume 3 classes with a dataset that has: **90%** of examples in **class 1**, **5%** in **class 2**, and **5%** in **class 3**
- We also use confusion matrix:
  - Each row represents a true label, and column elements represents the predicted label

# Example: 10 handwritten digit classification with Logistic Regression

Reference: Muller, Introduction to Machine Learning with Python

- Confusion matrix when applying [logistic regression](#) with default setting to the load\_digit data set

All digit Zero are classified correctly,

For digit 1, 39 examples are classified correctly, 2 samples are misclassified as 6, and 2 were misclassified as 8

- Precision, Recall can be evaluated for each class in a similar manner as two-class classification

- [Classification report in python](#)
- We can get average over all classes

# Evaluation Metrics in Python

```
from sklearn.metrics import confusion_matrix, precision_score,  
recall_score
```

```
PredictedOutput=Model.predict(X_test) # predicted output of  
classification
```

```
confusion=confusion_matrix(Y_test,PredictedOutput)
```

```
print(precision_score(Y_test,PredictedOutput))
```

```
print(recall_score(Y_test,PredictedOutput))
```

- Classification report for multiclass classification: [http://scikit-learn.org/stable/modules/generated/sklearn.metrics.classification\\_report.html](http://scikit-learn.org/stable/modules/generated/sklearn.metrics.classification_report.html)

ROC curve: [http://scikit-learn.org/stable/modules/generated/sklearn.metrics.roc\\_curve.html](http://scikit-learn.org/stable/modules/generated/sklearn.metrics.roc_curve.html)

```
from sklearn.metrics import roc_curve
```

```
FalsePositive, TruePositive, thresholds = roc_curve(Y_test, Fitted_Model.predict_proba(X_test)[:, 1])
```

Score of the positive class
